Single Stitch Mesh Fixation During Laparoscopic Trans-Abdominal Pre-Peritoneal Groin Hernia Repair: A Retrospective Study of 3800 TAPP Repairs

Hussain A*, Owers C*, Komolafe O*, El-Hasani S**

Abstract

Background: Two major techniques are currently used for groin hernia repair: the laparoscopic and the open repair. The aim of this study is to demonstrate the outcomes of single stitch mesh fixation in laparoscopic Trans-Abdominal Pre-Peritoneal (TAPP) repairs of groin hernia.

Material and Methods: Between 2000 and 2016, 3800 TAPP repairs were performed using a 10mm umbilical port and two 5mm ports on either side of the umbilicus, 5cm lateral to the rectus muscle. In this technique, a peritoneal flap is raised, the sac reduced, and 10x15cm polypropylene mesh fitted in the space to cover potential defects. This is then fixed by a single vicryl stitch at its upper edge with no additional tacking. The peritoneum is closed with a vicryl suture. A polydioxanone stitch is used to close the sheath at the umbilicus and monocryl sutures used for the skin. This study examines the complications, both early and late, from this large series of patients by retrospectively examining notes and GP referrals to our team or other colleagues within our department.

Results: A total of 3260 patients underwent 3800 TAPP operations during the 16-year period of this study: 3106 men and 694 women aged 17-92 years of age. Body mass index (BMI) ranged from 19-52. Of these TAPP repairs, 2258 were right sided, 1002 left and 540 were bilateral hernias. Types of hernia included: 3268 indirect, direct or pantaloons; 190 femoral; and 342 recurrent groin hernias. A significant number of cases were performed as day-case operation (2641). Complications identified included: 11 vas deferens injuries; 216 patients experienced post-operative urinary retention. Nine patients (0.23%) required conversion to open operation for a variety of reasons (see Table 1). Only five patients (0.13%) experienced a recurrence of their groin hernia.

Conclusions: Mesh fixation using single vicryl stitch results in negligible recurrence of the hernia in TAPP groin hernia repair.

Key Words

Trans Abdominal Pre-Peritoneal repair; Totally Extra Peritoneal repair

Introduction

The Trans-Abdominal Pre-Peritoneal (TAPP) groin hernia repair is a popular technique with the advantage of intraoperative peritoneal diagnosis (i.e. the type of hernial) and is a relatively less challenging approach. The Totally Extra Peritoneal repair (TEP) is another technique with excellent results. The debate as to which of these techniques is superior is ongoing with some studies demonstrating superiority of one technique over the other. However, the general consensus is that both techniques can produce equivalent, and satisfying, results, although some studies have demonstrated lower recurrence rates following open repair.

Laparoscopic repair is beneficial in numerous situations including bilateral or recurrent hernias, those keen for a shorter recovery period, and where patients specify a preference for laparoscopic surgery. Both methods are preferential to the open technique, although some studies show lower recurrence after open repair.

Whilst mesh fixation is not recommended in TEP repair, various different methods of mesh fixation have been suggested for TAPP repairs.

A potential cause of recurrence after TAPP repair could include the method of mesh fixation and alignment. Therefore, the aim of this study is to report the outcomes of using single stitch fixation for mesh in a large series of TAPP repairs.

Material and Methods

This study includes a retrospective review of prospectively collected data from 3800 patients. All patients were treated by one of two consultant surgeons (AH or SE), in one of two University Hospitals in the UK (Princess Royal in London or Don-

cater Royal Infirmary in South Yorkshire, following referral from their General Practitioner. Patients were assessed and consented for surgery by a consultant surgeon or their deputy. Consecutive patients over the age of 16 years, eligible for laparoscopic surgery were included, minimising selection bias. Patients unwilling to undergo TAPP repair; those unsuitable for general anaesthesia or laparoscopic surgery, patients with indirect hernia defects > 5cm, and those with recurrence following previous laparoscopic repair were excluded.

Demographic data was collected, including hospital number, date of birth, gender, date of admission, date of operation and date of discharge. Data specific to the operation was also collected including the type of groin hernia, the site of operation (right or left), BMI, the type and numbers of meshes used, post-operative complications (such as vas deferens injury, inferior epigastric artery injury, spermatic cord injury, bladder injury, bowel obstruction, conversion to open operation), post-operative morbidities and length of hospital stay. Post-operative morbidities of interest included: hernia recurrence, sepsis, infection, organ injury, urine retention and chronic groin pain. The usual Numeric Rating Scale NRS from 0-10 (11-point scale) was used for assessment of chronic groin pain. Finally, data pertaining to re-admission rates and the follow-up examination findings were recorded. All data was placed into an excel file sheet.

Post-operative assessment was carried out by the operating surgical team, therefore complete elimination of assessment bias was not possible. However, complications were recorded by the operating surgeon (AH or SE). In most cases, this assessment was performed at eight weeks, and in the absence of any complication requiring additional surgical input, the patient was discharged back to the care of their General Practitioner. Upon discharge, General Practitioners were instructed to refer the patient back to the surgical department in the event of any late complication or recurrence. For those with a complication (seroma, infection, recurrence, groin pain), further follow up was arranged until complete resolution of the morbidity, or a referral to another speciality occurred.

For the purposes of this study, early recurrence was defined as occurring during the first eight weeks post-operatively (by which time the patient was reviewed in the outpatient clinic). Late hernia recurrence was noted by a re-referral to the surgical department from primary or emergency care; where clinical or radiological recurrence was noted, these were managed by re-operation.

Simple statistical analyses were performed using an Excel spreadsheet.

Operative technique
A standard operating technique was used for all hernias. Patients are placed head down with the laparoscopic stack at the foot end, with the surgeon stood on the contralateral side to the hernia. TAPP repairs are performed using three ports; a 10mm umbilical utility port allowing for mesh introduction and camera use. Two 5mm ports are inserted on either side of the 10mm umbilical port, 5cm lateral to the rectus muscle on either side.

Upon entering the abdominal cavity, inspection for other pathology is made and the hernia identified. A peritoneal incision is made approximately 2cm above the edge of the apparent defect, medially extended to the lateral umbilical ligament, exposing the medial edge of the rectus; superiorly and laterally the dissection is extended as much as required to obtain 3-5cm overlap of the lateral edge of the hernia defect. Inferiorly, the peritoneal flap is dissected to overlap the pubic bone in the pre-vesical space, providing adequate space for the mesh to lie flat on the psoas muscle. In the male patient, the lower peritoneal flap is dissected off the vas and cord; in female patients, usual practice is to clip and transect the round ligament, which is then reflected with the peritoneum.

Hernias are repaired with polypropylene mesh size 10 x 15cm (Cousin Biotech, France). Irrigation of the mesh with antibiotics is not routinely performed. Mesh is aligned to the medial border of the contralateral rectus muscle. The mesh should lie flat on the abdominal wall without creases as these are believed to contribute to chronic pain via rolling and mesh displacement. If the first mesh does not adequately overlap the hernia defect superiorly or laterally then another mesh is inserted to provide sufficient overlap. There is a low threshold for the use of more than one mesh. Meshes are fixed using a single 2/0 vicryl stitch at the middle of the top edge of the mesh and away from the inferior epigastric artery.

Following satisfactory mesh placement, the peritoneum is closed using vicryl stitches. The 10-millimetre port is closed with polydioxanone (PDS) stitch(es) and the skin incisions closed with moncryl. Twenty millilitres of local anaesthetic (0.5% Marcaine) is infiltrated at the wounds.

Results
A total of 3260 patients underwent 3800 TAPP operations; 3106 (81.73%) males and 694 (18.26%) females aged 17-92 years. A wide range of body mass index patients were included (BMI range 19-52). Of these operations, 2258 (59.42%) were right
sided repairs, 1002 (26.36%) left sided and 540 (14.21%) were bilateral hernias. Types of hernia included: 3268 (86%) indirect, direct and or pantaloons; 190 (5%) femoral and 342 (9%) recurrent groin hernias. Two thousand six hundred and forty-one (69.5%) patients were treated as day case surgeries; 1159 (30.5%) were planned elective admissions and 74 (1.94%) were readmitted from day surgery (failed day case surgeries).

Although all operations were started as TAPP repairs, nine patients (0.23%) required conversion to open repair for a variety of reasons (see Table 2).

Of the documented complications, injury to the vas deferens was the most common organ injury, noted in 11 patients (0.28%). Post-operatively, 216 (5.68%) patients experienced urinary retention, which was the most common post-operative complication overall. Other complications included three mesh

Table 2: Complications
infections (0.07%) in inguinal hernias, two of which responded to antibiotics and one of which was salvaged by radiological aspiration of the abscess and antibiotics. Five cases (0.13%) of chronic groin pain were reported, also following inguinal hernia repairs. These patients were fully investigated by Ultrasound scanning (USG) and Magnetic Resonance Imaging (MRI) scans before referral to the pain team. Overall, only five (0.13%) port site hernias were reported and repaired by open surgical technique (tables 1 and 2). Five patients (0.13%) experienced recurrence of their inguinal hernia, which was managed by open repair. No complications were recorded following femoral hernia repairs.

Discussion
TAPP repair of the groin hernia is a popular technique and has the advantages of being diagnostic (i.e. able to determine the type of hernia), unlike the TEP technique. Both techniques provide comparable results with regards to mesh infection, recurrence, chronic pain and quality of life. These results were clearly demonstrated by the low incidence of complications in this, one of the larger case series published in the literature.

There are numerous variations in surgical technique which can be used during TAPP repair. For example, the authors would advocate that it is mandatory to dissect and reduce the hernia sac. This is in order to decrease the risk of recurrence. In TAPP repair for femoral hernias, it is almost always necessary to incise the medial edge of the femoral ring for safe and total delivery of the sac and contents from the femoral canal, without jeopardising the femoral vein. For the indirect inguinal hernia sac, care is taken to reduce the sac without injuring the spermatic cord or the vas.

For sacs that are stuck deep in the inguinal canal towards the scrotum, the dissection may cause unnecessary bleeding or injury to the cord, so there should be a low threshold to circumcise the sac as safely as possible distally, toward the scrotum. When the sac is circumcised, it is important that the hole in the peritoneal flap is closed using a Vicryl stitch. Should a long indirect inguinal sac be reduced, then it is necessary to ligate this sac with Vicryl in order to avoid leaving a potential space for further bowel herniation.

An interesting point for debate during TAPP repair of groin hernias is whether or not to fix the mesh. Numerous methods of mesh fixation have been described in the literature. Studies have shown that mesh fixation is unnecessary in most patients and may not affect the incidence of chronic groin pain, the main concern of those surgeons who do not advocate mesh fixation. The authors in this study used a single stitch mesh fixation, as it was considered effective in reducing the incidence of mesh slippage and therefore may have led to a decreased rate of hernia recurrence. The use of tackers to fix the mesh is controversial as it is costly. Given that this case series included 3800 repairs, suture fixation rather than specialist tacking devices is estimated to have saved the equivalent of approximately $130 000 to 200 000. However, the advent of new meshes which do not require fixation removes the need for suturing or tacking and may therefore negate this concern. However, the cost of this type of mesh may have significant financial implications, especially when used in a series as large as the one reported in this article (3800 repairs). In the author’s experience, mesh fixation to the edges of the defect (with sutures, or more commonly, with takers) is only required in large, wide hernias (more than 5cm defect) in order to prevent protrusion of the mesh through the defect into the scrotum; these patients were not included in this study. Avoiding use of a tacking device can decrease the cost of the operation; it is also potentially associated with less neuralgic pain, although some studies debate this issue. Following placement of the mesh (with or without fixation), meticulous closure of the peritoneal defect and any peritoneal defect using Vicryl stitches is crucial to avoid potential herniation of the bowel which may require further surgery.

In terms of which mesh to use, in the experience of the operating surgeon (AH), absorbable synthetic materials are more susceptible to bacterial colonisation than non-absorbable materials, thus polypropylene mesh is was used for all patients in this series. In spite of the fact that mesh infection is very low, supported by this study, the first two mesh infections were treated with antibiotics. However, one patient who presented with pain and raised inflammatory markers 15 days following surgery had formed an abscess cavity around the mesh; this was subsequently treated by ultrasonography guided aspiration in addition to antibiotics. All meshes were salvaged.

The causes of recurrence after TAPP repair are variable and it cannot be categorically stated that single stitch fixation of the mesh is solely responsible for our low recurrence rate. It also difficult to conclude that operative and post-operative bleeding is less with single stitch fixation compared to tackers, although the use of multiple fixation points using a tacking device is more likely to injure vessels in the dissection field and cause bleeding this risk is significantly reduced with single point fixation. However, the cost of surgery is most certainly reduced and the authors hypothesise that it may most likely reduced the incidence of pain after surgery given that
previous studies have linked pain to the use of tacker. There is a debate about the discovery intraoperatively of contralateral (and often incidental) hernias, and whether or not to repair them at the same operative sitting. The authors would advocate that this can, and may, be done safely in a selected group of patients (if they are fit enough for laparoscopic surgery, without significant comorbidities), as TAPP repair lends itself well to this technique. The size of the mesh and the nature of the technique imply that contralateral hernias are automatically repaired. In the authors’ routine practice, contralateral or concurrent hernias are repaired during the same operation; all patients were informed during the consent procedure that an incidental hernia on the contralateral site will be repaired, especially if the patient declares minor symptoms on that side. However, long operative time, the risk of surgical emphysema, patient age and physiology is taken into consideration and where the risk is deemed too high, contralateral incidental hernias may be left alone, or a future repair planned if the patient is keen.

Post-operative pain can be difficult to manage, especially when chronic. Patients are usually pain free by the end of the first post-operative week. Occasionally, patients complain of groin discomfort, describing “twinges” when they widely abduct or flex the thigh.

In the authors’ experience, most of these symptoms dissipate within three months following surgery. On rare occasions, the patient may complain of chronic groin pain after this time. Within this series, this occurred in five (0.13%) patients. Clinical and radiological assessment (ultrasound and MRI examinations) often do not show any abnormality, and local wound exploration may exacerbate the problem. In most cases, the authors would advocate referral to the chronic pain specialist. Patients may also complain of paraesthesia on the upper lateral aspect of the thigh along the distribution lateral cutaneous nerve. In this series, where patients complained of this loss of sensation, follow up was extended for up to 18 months; in all cases the paraesthesia sensation either improved or resolved.

Recurrence following any type of hernia repair is widely acknowledged, and many new operative techniques have been suggested over the years to try to prevent this complication from occurring. One study published in 2003 reported recurrence rate of 2.3% however a later study showed the recurrence rate to be as little 0.68% after five years.

Within our study, a very low recurrence rate (five patients; 0.13%) was demonstrated. Recurrence after TAPP repair is most likely to occur if the medial dissection is short of the midline, and if the lower edge of the mesh is not placed flat, as it can roll up with consequent herniation through the inguinal or femoral canal. If the mesh is not fixed to the edges of a large defect, there is the potential for herniation into the inguinal canal. Therefore, it is important to ensure that the mesh is large enough to provide adequate coverage of the hernia defect and surrounding tissues.

Laparoscopy and exploration of the groin area can be offered to active patients who present with chronic groin pain with no gastrointestinal or urological symptoms and where radiological investigation has excluded any musculoskeletal cause for their pain. When performed, the peritoneal flap should be dissected, as, in the authors experience, there are occasions where there may be a hernia, but the defect is filled with pre-peritoneal fat without a peritoneal sac. Therefore, diagnosis can only be made by peritoneal dissection. Dissection for groin pain is the same as dissection for a hernia. Out of the 117 patients who had laparoscopic exploration of the groin for chronic pain and repair of a previously undiagnosed hernia with mesh, 91 (78%) patients had complete relief of their pain post-operatively. However, these patients should be selected carefully, often after consultation with orthopaedic colleagues.

With regards to post-operative complications, seromas may occur due to the collection of reactionary serous fluid in the potential space left in the groin region following hernia reduction. All patients should be counselled regarding the possibility of seroma formation; in the event of seroma occurrence, they should be reassured at any subsequent follow-up or hospital visit that this is not a hernia recurrence. This is particularly important for large or inguino-scrotal hernias which may have a larger incidence of seroma. The majority of seromas are asymptomatic; however, for those patients with tenderness or symptoms suggestive of early infection, seromas can be aspirated under strict aseptic technique. In the experience of these authors, where there is persistence on clinical examination for more than three months following the operation, the presentation is often an organised haematoma rather than a seroma, as seromas are usually absorbed before three months.

Retention of urine following hernia repair is common in both the laparoscopic and open approach. Two hundred and sixteen (5.68%) patients developed retention in this series. Distension of the bladder...
TAPP repair of groin hernia using single stitch mesh fixation is safe, effective and associated with negligible rate of recurrence and chronic groin pain in a large cohort of patients. The authors therefore recommend the use of this technique in routine clinical practice.
